Abstract—Direction-of-arrival (DoA) estimation is a mature topic with decades of history. Despite the progress in the field, very few papers have looked at the problem of DoA estimation with unknown dynamic range. Consider the case of space exploration or near-field and far-field emitters. In such settings, the amplitude of the impinging wavefront can be much higher than the maximum recordable range of the sensor, resulting in information loss via clipping or sensor saturation. In this paper, we present a novel sensing approach for DoA estimation that exploits hardware-software co-design and is pivoted around the theme of unlimited sensing. On the hardware front, we capitalize on a radically new breed of analog-to-digital converters (ADCs) which, instead of saturating, produce modulo measurements. On the algorithmic front, we develop a mathematically guaranteed DoA estimation technique which is non-iterative and backwards compatible with existing DoA algorithms. Our computer experiments show the efficiency of our approach by estimating DoAs from signals which are orders of magnitude higher than the ADC threshold. Hence, our work paves a new path for inverse problems linked with DoA estimation and at the same time provides guidelines for new hardware development.

Index Terms—Direction of arrival (DoA) estimation, multi-channel, non-linear sensing, sensor arrays, sampling theory.

I. INTRODUCTION

The art of using multiple sensors for spatio-temporal acquisition of information has several decades of history. One of the core applications of sensor arrays is direction-of-arrival (DoA) estimation which dates back to the pioneering work of Marconi in the beginning of the 20th century [1]. While DoA estimation is a mature topic [2], the advent of new hardware and applications continually pushes the envelope of the DoA algorithmic machinery. In the last many years, research efforts have been mainly focused towards exploring new array geometries [3]–[5] and designing algorithms for high resolution DoA estimation [6], [7].

DoA Estimation and Dynamic Range Problem. Our work is concerned with a different class of DoA estimation problems, where the amplitude range of the impinging signal is unknown and possibly much larger than the maximum recordable voltage of the analog-to-digital converter (ADC). This problem arises from practical contexts. We list two examples below.

• In space explorations, scientific equipment in the probe employs sensor arrays for various tasks such as source localization and sub-surface mapping. In foreign environments, for instance radar systems on lunar surfaces [11], the range of signal amplitudes is unknown and automatic gain control (AGC) is employed either during capture or in post-processing. NASA’s Apollo Mission report [12] elaborates on the omnipresent use of AGCs and reports the sensor saturation problem (cf. pg 43, [12]). Even if the ADCs (equipped with AGCs) are calibrated, bursts and spikes [13] can saturate the sensor array, resulting in clipped measurements. This typically happens in the case of radars and seismic systems.
• A more familiar example of sensor array saturation stems from the near-far problem. Suppose that only two emitters are considered, and one of them is much closer to the receiver than the other. Then, the ADC can either focus on the near-field emitter, drowning the far-field emitter in quantization noise, or aim at retrieving the information of the far-field emitter, clipping the samples of the near-field emitter [14].

Beyond the problems listed above, the general trend in the recent years has been to use ADCs which can work with wideband receivers. It is well established that wideband ADCs require higher dynamic range [15], [16]. Surprisingly,
Despite the significant advancements in DoA estimation, very few papers pose the problem with dynamic range constraints. To this end, a notable example is the work of Bar-Shalom and Weiss [17] who present the idea of one-bit ADC based DoA estimation. This approach circumvents the problem of clipping and even using AGCs. However, the one-bit mode of operation is at the other end of the spectrum of solutions—entire signal information is lost and only DoAs can be estimated. While this low-complexity solution is aptly justified for wireless communications, in many applications it is of interest to recover the signal itself. For example, in space exploration, experiments entail exorbitant costs and are non-repeatable. Similarly, in bio-medical [18] and ultrasound [19] applications, the signal itself encodes important information.

**Solution via Modulo Non-Linearity.** In what follows, we will present a new approach to the DoA estimation problem based on co-design of hardware and algorithms. Our work capitalizes on the recent developments around unlimited sensing [8]–[10]. Instead of working with conventional, point-wise samples of a function, which may be clipped, we opt to use folded amplitudes in the interval $[-\lambda, \lambda]$, where $\lambda > 0$ is the maximum recordable voltage of the ADC. On the hardware side, injecting modulo non-linearity in the sensing process results in folded measurements, as shown in Fig. 1. Mathematically, this can be written in terms of the following operator,

$$\mathcal{F}_\lambda : t \mapsto 2\lambda \left( \left\lfloor \frac{t}{2\lambda} + \frac{1}{2} \right\rfloor - \frac{1}{2} \right),$$

(1)

where $\mathcal{F}_\lambda (\cdot)$ is the conventional, centered modulo operation, and $\lfloor t \rfloor \triangleq t - \lfloor t \rfloor$ denotes the fractional part of $t$. Hence, arbitrarily high amplitudes beyond the dynamic range of the ADC are folded back into the recordable range $[-\lambda, \lambda]$ (cf. Fig. 1). Thanks to the recent, radical advances in ADC design technology, such non-linearities can be implemented via folding or self-reset ADCs [20], [21]. For further discussion on the link between folding ADCs and modulo non-linearities, we refer the readers to [9]. Even when the problem of recovering measurements from modulo samples is highly ill-posed, a sampling theorem and algorithm applicable to bandlimited functions have been already proposed in [8], [9]. The main result is as follows,

**Theorem 1** (Unlimited Sampling Theorem [8]). Let $x(t)$ be a continuous-time, finite-energy, bandlimited function with maximum frequency $\Omega$ and let $y[n] = \mathcal{F}_\lambda (x(nT))$ be its modulo samples with sampling rate $T$. Then, a sufficient condition for recovery of $x(t)$ from its modulo samples (up to an additive multiple of $2\lambda$) is $T \leq 1/2\Omega\epsilon$.

Remarkably, this sampling theorem does not depend on $\lambda$ and depends only on the signal bandwidth; just like Shannon’s sampling theorem. For a detailed discussion on the sampling theorem and associated algorithm, we refer the reader to [9].

**A. Contributions**

- We take a first step towards the formalization of the DoA estimation problem based on low-dynamic-range, modulo samples $y[n] = \mathcal{F}_\lambda (x(nT))$.
- We provide a simple recovery algorithm that is backwards compatible with known DoA estimation and beamforming methods. The recovery guarantees are agnostic to $\lambda$.

**B. Advantages of DoA Estimation with Modulo Samples**

**Compatibility with Known DoA Estimation Techniques.** An appealing feature of our method is its simplicity. Although our approach starts with non-linear, modulo samples $y[n]$, we show that existing DoA methods can be applied on a transformed version of $y[n]$, that is, $T(y[n])$. As it will be shown, $T(y) = \mathcal{F}_\lambda (\Delta^K y)$ is a point-wise, single-shot mapping, where $\Delta^K$ is the finite difference operator of order $K$. With $T$, DoA estimation is mathematically guaranteed to succeed provided that we choose $(T, K)$ according to the unlimited sampling theorem (cf. Theorem 1 and [9]).

**Reduction in Computational Complexity** What distinguishes this paper from our preceding works [8], [22], [23] is that here, (a) we are working with multi-channel measurements and (b) DoAs can be directly estimated from the modulo samples; there is no need to reconstruct the signal. This results in a reduction of both the computational requirements and the sampling density.

**Compatibility with Beamforming.** Compared to 1-bit encoding methods, a distinct advantage of our approach is that we can perform beamforming. In fact, we can perform beamforming directly on $T(y[n])$, since $\Delta^K$ does not affect the space-dimension of the data. Such invariance allows retrieving only the unfolded samples from the desired sources instead of repeating the whole process on each antenna individually, which further reduces the complexity.

**II. Problem Setup**

**Notation.** Continuous functions and discrete sequences are represented by $x(t), t \in \mathbb{R}$ and $x[n], n \in \mathbb{Z}$, respectively. Matrices and vectors are written in capital and small, boldface font, respectively. For a matrix $X$, we define $[X]_{m,n}$ as the entry in the position $(m,n)$ where we start counting from zero. We use $X^H$ and $X^\top$ to denote conjugate-transpose and transpose of matrix $X$, respectively. The covariance of a matrix $X$ is written as $\mathbb{R}(X) = XX^H$. We use $\text{ker}(X)$ and $\text{span}(X)$ to denote the kernel and span of a matrix, respectively. Function and sequence spaces are denoted by $L_p$ and $l_p$, respectively and the corresponding norms are defined by $\| \cdot \|_{L_p}$ and $\| \cdot \|_{l_p}$. When $p \to \infty$, the norms denote the max-norm. A function $x$ bandlimited to maximum frequency $\Omega$ is denoted by $x \in B_\Omega$ while $x \in PW_\Omega$ denotes a function in the Paley–Wiener class of bandlimited and square-integrable functions, $x \in B_\Omega \cap L_2$.

**A. Data Model**

We consider the standard setup in sensor array processing [1]. Suppose that $M$ narrow band sources $\{s_m(t)\}_{m=0}^{M-1}$ with DOAs $\Theta = \{\theta_m\}_{m=0}^{M-1}$, impinge on a uniform linear array
(ULA) with \( L \) sensors. The resulting data model for the \( l \)th sensor \((l = 0, \ldots, L - 1)\) is written as,

\[
x_l[n] = \sum_{m=0}^{M-1} a_l(\theta_m) s_m[n]
\]

where,

- \( x_l[n] = x_l(nT), n = 0, 1, \ldots, N - 1 \) is the sampled waveform corresponding to the \( l \)th sensor, which can be stacked in the matrix \( X \) as \( [X]_{l,n} = x_l[n] \).
- \( a_l(\theta_m) \) is the \( l \)th entry of the array steering vector given by,

\[
a(\theta_m) = \left[ 1 \ e^{jd\pi \sin(\theta_m)} \ e^{jd\pi(L-1) \sin(\theta_m)} \right]^T
\]

where the \( \theta_m \)’s are all distinct. The resulting matrix is,

\[
A_\Theta = \left[ a(\theta_0) \ldots a(\theta_{M-1}) \right].
\]

- \( s_m[n] = s_m(nT), n = 0, \ldots, N - 1 \) are the samples of the \( m \)th narrowband waveform, which can be stacked in the matrix \( S \) as \( [S]_{m,n} = s_m[n] \). Here, we will assume that \( s_m \in \text{PW}_\Omega \) (Paley-Wiener class), and hence \( T \leq \pi/\Omega \) according to Shannon’s sampling theorem.

In a compact form, given \( M \) sources, \( L \) sensors and \( N \) time-samples, the relationship between the matrices \( X, A_\Theta \) and \( S \) is given by,

\[
X = A_\Theta S. \tag{4}
\]

In our work, we aim to recover the unknown DOAs \( \Theta \) from modulo measurements. Since the entries of the folding operator are complex-valued, the modulo operator \( \mathcal{M}_\lambda (\cdot) \) should be interpreted in the following sense,

\[
\mathcal{M}_\lambda(t) : t \in \mathbb{C} \to \mathcal{F}_\lambda (\mathbb{R}(t)) + j\mathcal{F}_\lambda (\mathbb{R}(t)), \tag{5}
\]

The DOA estimation problem boils down to recovering \( \Theta \) from point-wise non-linear measurements,

\[
Y \doteq \mathcal{M}_\lambda(X) = \mathcal{M}_\lambda(A_\Theta S). \tag{6}
\]

The definition of the folding operator \( \mathcal{M}_\lambda \) in (5) allows us to map \( X \in \mathbb{C}^{L \times N} \) to \( Y \in \mathbb{C}^{L \times N} \). A graphical representation of the setup is shown in Fig. 1.

\section{Geometry of the DoA Estimation Problem}

Existing techniques for DoA estimation cannot be directly applied in this scenario. To give the reader an intuitive understanding, consider the geometry of the eigen-decomposition and the rank constraint on \( \mathbb{R}(X) \); the covariance matrix of the conventional data samples. It is well known that the eigen-decomposition of \( \mathbb{R}(X) \) takes the form of,

\[
\mathbb{R}(X) = A_\Theta \mathbb{R}(S) A_\Theta^H = U \Lambda U^H. \tag{7}
\]

The diagonal matrix \( \Lambda \) is at most rank \( M \) (in the absence of noise). This property is lost when working with data matrix \( Y \).

To see this, let us recall the \textit{Modulo Decomposition Property} [9] which allows to write \( x(t) = \mathcal{M}_\lambda(x(t)) + \mathcal{D}_\lambda^Y(t) \) where \( \mathcal{D}_\lambda \in 2\lambda \mathbb{Z} \) is a simple function. In the context of our work, modulo decomposition implies that the data matrix can be decomposed as \( X = Y + \mathcal{D}_X^Y \), and hence,

\[
\mathbb{R}(Y) = \mathbb{R}(X) + \left( \mathbb{R}(\mathcal{D}_X^Y) - \left( X \mathcal{D}_X^Y + \mathcal{D}_X^X \right) \right). \tag{8}
\]

Consequently, \( \mathbb{R}(Y) \) can be interpreted as a noisy version of \( \mathbb{R}(X) \) in (7). Therefore, standard techniques cannot be applied unless a denoising strategy is employed.

\section{DOA Estimation From Modulo Samples}

\subsection{Intuition and Overview of the Approach}

In this work, starting with sampled data matrix \( Y \), we apply a transformation \( \mathcal{J} \) such that \( Z = \mathcal{J}(Y) \) maps to the original signal subspace \( X \) but not necessarily to \( X \) itself. Once this is possible, we can use existing DoA estimation methods. Our approach leverages the idea that higher order differences taken over the samples (denoted by \( \Delta^K \)) and the modulo operator \( \mathcal{M}_\lambda (\cdot) \) commute in a certain sense [9]. For a smooth sequence, \( x[n] = x(nT) \), the application of \( \Delta^K \) has a shrinking effect on the derivative of the same function which is controlled by \( T^K \). Hence, for a certain choice of sampling rate \( T \) and difference order \( K \), it is possible to shrink the amplitudes of a sequence arbitrarily. Once the difference sequence is smaller than \( \lambda \), the folding operation in (6) has no effect. This is because for any \( \|a\|_{\ell_\infty(\mathbb{R})} \leq \lambda \), we have that \( \|a\|_{\ell_\infty(\mathbb{R})} = \mathcal{M}_\lambda(a[n]) \).

The net effect is that folding has no impact on the higher order differences and hence, starting with modulo measurements, we can access the higher order differences of the original sequence using \( \mathcal{J}(Y) = \mathcal{M}_\lambda(\Delta^K(Y)) \). Now, since differences are linear operators, their action on the subspace of bandlimited functions preserves the subspace structure.

\subsection{Recovery Guarantees}

Formally, let \( x^{(K)}(t) \) denote the \( K \)th order derivative of \( x(t) \) and \( (\Delta^K x)[n] \) be the finite difference of the sequence \( x[n] \), with \( (\Delta x)[n] = x[n+1] - x[n] \). The following lemma gives a relation between \( \Delta^K x \) and \( x^{(K)} \) in terms of the max-norm.

\textbf{Lemma 1} (Difference-Derivative Inequality [8], [9]). For any \( x(t) \in C^K(\mathbb{R}) \cap L_\infty(\mathbb{R}) \), its samples \( x[n] \) satisfy,

\[
\|\Delta^K x\|_{\ell_\infty(\mathbb{R})} \leq (Te)^K \|x^{(K)}\|_{L_\infty(\mathbb{R})}. \tag{9}
\]

Using \( T < 1/e \) allows us to shrink the amplitudes on the right hand side of (14). Typically, it is much easier to estimate the maximum value of the function than a bound on its derivative. To bound the right hand side of (9), we invoke the well known Bernstein’s inequality for bandlimited functions; for all \( x \in B_\Omega \), we have, \( \|x^{(K)}\|_{L_\infty(\mathbb{R})} \leq \Omega^K \|x\|_{L_\infty(\mathbb{R})} \). By combining this with (9), we obtain the following bound in [9],

\[
\|\Delta^K x\|_{\ell_\infty(\mathbb{R})} \leq (T\Omega e)^K \|x\|_{L_\infty(\mathbb{R})}. \tag{10}
\]

Let \( B_x > \lambda \) be a known upper bound on \( x(t) \). Choosing \( T\Omega e < 1 \) in (10) ensures \( (T\Omega e)^K B_x \leq \lambda \), for \( K \) given by

\[
K \geq \left\lceil \frac{\log \lambda - \log B_x}{\log (T\Omega e)} \right\rceil, \tag{11}
\]
which is independent of $M$. Thus, letting $T < 1/\Omega e,$
\[
\|\Delta Kx\|_{\ell^\infty(\mathbb{R})} \leq \lambda \Rightarrow \Delta Kx = M\lambda (\Delta Kx).
\] (12)
To relate higher order differences of $x$ with the measurements $y$, we use the following proposition [9].

**Proposition 1.** For any sequence $x[n]$ it holds that
\[
\mathcal{M}_\lambda (\Delta Kx) = \mathcal{M}_\lambda (\Delta K (\mathcal{M}_\lambda (x))).
\] (13)

In our setup, since the time-domain samples are arranged along the row-dimension of $L \times N$ matrix $[X]_{l,n} = x_l(nT)$, the difference operator acts over each row independently,
\[
[\Delta KX]_{l,n} = (\Delta Kx_l)(nT) = [XD_K]_{l,n}
\] (14)
where $D_K \in \mathbb{R}^{N \times (N-K)}$ is the matrix corresponding to $\Delta K$ and $D_0 = I$ (identity matrix). Combining (13) and (12), we obtain the link between higher order differences and the modulo samples,
\[
\Delta Kx = \mathcal{M}_\lambda (\Delta K g) \iff XD_K = \mathcal{M}_\lambda (YD_K).
\] (15)

We summarize our main result in the following theorem.

**Theorem 2 (US-DoA).** Let \{sm\}m=0M−1 ∈ Bπ be M, bandlimited functions and sm[n] = sm(nT), n = 0, ..., N − 1, be the samples with sampling rate $T$. Furthermore, let the modulo samples be stacked in the data matrix $Y = \mathcal{M}_\lambda (A_\Theta S)$ in (6) with $A_\Theta$ defined in (3). Provided that the sampling rate satisfies the sampling bound, $T < 1/2\Omega e$ and for some $N > K$, choosing,
\[
B_x \geq \max_{0 \leq l \leq L-1} \|x_l\|_{\ell^\infty(\mathbb{R})} \text{ and } K \geq \left[\frac{\log \lambda - \log B_x}{\log (T\Omega e)}\right]
\] results in (15), $XD_K = \mathcal{M}_\lambda (YD_K)$.

Instead of recovering $X$ from $XD_K$ (higher order differences), which was the case in previous works on the topic of unlimited sampling [8], [22], [23], here we are interested in estimating DoAs. To this end, let us denote,
\[
Z = \mathcal{M}_\lambda (YD_K) = XD_K.
\] (16)
Accordingly, we obtain the eigenvalue decomposition of the covariance matrix, $\Sigma(Z) = U\Lambda U^H \equiv A_\Theta \Sigma (\bar{S}) A_\Theta^H$, where $\bar{S} = SD_K$. This shows that the operator $\Delta K$ preserves the array manifold. For subspace based techniques, such as MUSIC or ESPRIT the following result has to be considered.

**Proposition 2.** Let $S$ be an arbitrary, full-rank, matrix, such that $S_k = SD_k$ is full rank, and let $X_k = A_\Theta SD_k$ define a sequence of matrices. Then, $\text{span}(\Sigma(X_0)) = \text{span}(\Sigma(X_k))$.

According to Proposition 2, starting with modulo measurements $Y$, we can map them to the space spanned by the covariance of conventional samples $X$. This is advantageous because existing methods can be readily applied. This results in the following recovery algorithm.

**Recovery Algorithm**

**Inputs:** Data matrix of modulo samples $Y$ in (6).

**Number of sources $M$.** An estimate on the upper bound, $B_x \geq \|\{x_l\}_{l=0}^{L-1}\|_{\ell^\infty(\mathbb{R})}$.

**Step 1:** Compute $K$ using (11).

**Step 2:** Compute $Z$ using (16).

**Step 3:** Evaluate SVD, $Z = USV^H$ or $\Sigma(Z) = US^2U^H$.

**Step 4:** Use traditional techniques for DoA estimation.

**Output:** $\Theta = \{\theta_m\}_{m=0}^{M-1}$.

In the above recovery method, depending on the DoA estimation technique employed, specific constraints over the number of sources $M$, samples $N$ and array elements $L$ should be considered [1]. For example, for MUSIC and ESPRIT algorithms, the requirement is that $L > M$.

**IV. NUMERICAL DEMONSTRATION**

In this section, we provide examples of DoA estimation. Furthermore, we consider the noisy case which shows that our approach is empirically stable in the presence of perturbations.

**Noiseless Case** We consider $M = 4$ transmitted, bandlimited signals $s_m \in B_\pi$ which are randomly generated. We use $N = 8$ with $T = (2\pi e)^{-1} = 1/100$. The corresponding DoA angles $\{\theta_m\}_{m=0}^{3} \equiv 3, 15, 45$ and 87 degrees. We consider a ULA with $L = 11$ elements. Inter-element spacing is set to half a wavelength. Based on the experimental parameters, we construct the ground truth $X$ and choosing $\lambda = 0.2$ we obtain $Y$. A row of $X$ and corresponding $Y$ is shown in Fig. 2(a). The value of $B_x$ is assumed to be known. With these parameters, we estimate $K$ using (11). We perform the DoA estimation on $Z$ in (16) and $X$, using the MUSIC algorithm. As shown in Fig. 2(b) for a given row, $Z$ is equal to $XD_K$. The MUSIC pseudo-spectrum is shown in Fig. 2(c). The results for $Z$ and $X$ are equal up to MATLAB’s numerical precision.

**Noisy Case** Next, we evaluate our algorithm’s performance in the case of noise. To this end, we consider the additive white Gaussian noise (AWGN) model. For comparison, we add noise to the conventional and modulo samples. As we do not use any denoising methods, this experiment serves as an empirical test of our algorithm’s stability. We use the same experimental parameters as above, but with $N = 800$ and retrieve the DoAs using the ESPRIT algorithm with $M = 2$ (angles are 3 and 15 degrees). The SNR varies from 0 to 50 dB. The accuracy of the method is assessed using the MSE between the estimates and the ground truth. The experiment is averaged over 5000 trials for both noisy versions of $X$ and $Y$, respectively. The results are shown in Fig. 2(d). As expected, for low SNR, our method is unable to work with noisy measurements. Nonetheless, as the SNR increases, the method reaches a performance comparable to operating directly with the unfolded samples. The formal integration of noise into US-DoA is left for future research.

**V. CONCLUSIONS**

In this work, we presented a novel sensing approach for DoA estimation that is based on modulo non-linearity. Our work can tackle arbitrarily high-dynamic-range signals without running into the saturation problem. This is well suited for
applications where ambient dynamic range is unknown or near field emitter/interferer may cause sensor saturation. The key advantages of our method are (a) non-iterative recovery, (b) backwards compatibility with known DoA estimation methods and (c) preservation of the original, unfolded signal. This allows for applications such as beamforming which is not possible with other alternatives such as the 1-bit architecture. Finally, our approach is based on a new kind of non-linear sensing setup, which leads to several interesting research questions on both the algorithmic and hardware fronts.
